[1960] 7p.

DESCRIPTORS: *Alloys, *Electrodeposition, Copper
alloys, Cobalt alloys, Nickel alloys, Zinc alloys,
Lead alloys.

During the deposition of copper-lead and nickel-cobalt alloys, changes in potential that are observed have a large period of fluctuation, within which fluctuations of smaller period occur. The large periods of change in cathode potential noted in oscillograms obtained during the deposition of nickel-cobalt and copper-lead alloys correspond to the time for the formation of one layer in the deposits. In order to ascertain the nature of the variations in potential in the process of deposition of an alloy which is accompanied by the evolution of hydrogen, oscillograms were obtained for the process of discharge of ions of hydrogen on copper and zinc from a cyanide solution, and it was shown that the cathode potential varies periodically during the discharge of the hydrogen ions. The fluctuations in potential with a short period during the deposition of alloys are due to the evolution of hydrogen. No substantial difference was found in the nature of the changes in cathode potential during the process of discharge of ions with the formation of an alloy that can be related to the different types of fusion diagrams. a result of interaction of components during the formation of an alloy. The magnitude of the shift can be calculated directly from thermodynamic data, as well as from data on the free energy change obtained by measuring vapor pressure changes of the system, or from data on electromotive force of a suitably constructed circuit. The values of quantities of the energy of mixing of the components necessary for the calculations may be determined by the use of standard thermochemical methods, as well as from data obtained from experimentally constructed equilibrium diagrams using a method which is a reverse of that proposed in the literature for theoretical construction of diagrams from thermochemical data. Practical and convenient methods for changing from integral values of energy of mixing to differential values, which are necessary for evaluation of the processes taking place during the electrodeposition of an alloy on a cathode, are examined. with the value calculated on the basis of data for the change in its partial thermodynamic potential. The possibility of using the data on the shift in deposition potentials for calculations in the reverse direction, i. e., for approximate computations of differential heats of solution of some unexplored systems is pointed out. An advantage of this method is the considerable simplification of the working procedure. The possibility of incorporating aluminum into the deposit during the deposition of nickel is demonstrated. metals at the expense of energy of interaction during alloying and the equalization of deposition potentials of metals is examined. It is shown that even in the presence of considerable energy of interaction and shift in the deposition potentials of metals toward the more positive side, potential equalization may not even be observed if the magnitudes of the shift for the two components are of the same order. On the basis of an investigation of the dependence of the change in the free energy of the system during the formation of an alloy on its composition it is shown that the energy of interaction may lead to equalization of deposition potentials of metals only up to a certain definite concentration of the electronegative metal in the alloy.

Experiments are described which showed that, due to the increase in stresses and strains of expansion in coatings, the coercive force of electrolytic nickel deposits increases when the pH of the electrolyte is increased. Under conditions where the pH considerably exceeds the value corresponding to the limit of the formation of the hydrate in the solution, a change is possible in the character of crystallization of the

deposits. This leads to a sharp decrease in the value of coercive force. On the basis of a comparison of the structurally sensitive magnetic characteristics of nickel deposits obtained under different conditions, it was determined from the quantity of hydrogen included in such deposits that hydrogen is not the principal reason for internal stresses and strains observed in the deposits. The amount of hydrogen in nickel deposits depends upon its dispersity and the degree of distortion of the crystal lattice.
